The Carbon Footprint of Electric Vehicle Batteries

Fossil fuel consumption by road transport vehicles generates approximately twenty percent of the United States' annual carbon emissions, also known as greenhouse gases (GHGs). Vermont, emissions generated by road transport vehicles contribute approximately twenty percent of the state annual GHGs.² Interest in reducing these numbers through policy and new technology has resulted in the promotion of electric vehicles (EVs) as the key to achieving transportation systems.³

The level of GHG emissions reduction an EV can deliver depends upon a variety of factors, but not limited to the vehicle's size and weight; the type of drive train; the energy sources from which it is powered; and the number of

2. A plug-in hybrid electric vehicle (PHEV) is powered by electrical energy, but also utilize conventional or alternative fuels extended range. The battery is charged by plugging it to external sources and through regenerative braking.
3. A battery electric vehicle (BEV) is powered entirely by electrical energy from an external electrical source charging; these vehicles burn no fuels and no direct emissions.

While an electric vehicle typically produces fewer direct emissions than a comparably sized conventional vehicle, the measure of its carbon footprint incorporates indirect emissions. These include GHGs from all the energy consumed throughout the production, usage, and disposal of the vehicle. A primary contributor to an EV's indirect emissions is its lithium-ion battery.

Life Cycle Assessment of an EV Battery

Notably, the proprietary nature of enterprise research and development limits the availability of battery production data on their processes and energy consumption for these two stages.¹⁵ Without the benefit of primary data, researchers rely on assumptions about the CTG phase when modelling lithium-ion battery overall emissions impacts carbon footprint. As a result, CA studies vary widely in scope and methodology, and collectively a broad range of outcomes and interpretations.¹⁶

A primary driver of variance comes from differing assumptions about the direct energy demands of the materials production and the battery assembly. Further differences stem from assumptions regarding cell chemistry and pack design. The range of estimates in the literature illustrated by Figure 1, indicates a high degree of uncertainty involved in GHG emissions.¹⁷

Seeking to address the variance in the lifecycle assessments of CTG emissions, affiliated with the Norwegian University of Science and Technology analyzed the underlying data from lifecycle assessment studies on lithium-ion batteries. After examining the key assumptions and differences, the group concluded that the primary source of emissions in the cradle-to-gate phase stems from materials production specifically, cell manufacture. Furthermore, they contend that the source of GHG emissions over the life cycle of a lithium-ion battery accumulates during the cradle-to-gate phase contributing an average 157kg CO₂e per kWh of battery capacity carbon footprint.¹⁸

On the top ten list of today's highest-selling electric vehicles, plug-in hybrid utilize batteries which range from 8kWh to 17kWh, while batteries powering full electric vehicles range from 40kWh to 100kWh. Thus, the manufacture of PHEV batteries produces 2.6 metric tons of GHG emissions on average, the manufacture of larger BEV batteries produces 11.8 metric tons of GHG emissions on average.

Well-to-Wheels

The current use portion of an electric vehicle's overall lifecycle is highly variable in terms of emission production. This makes measuring the carbon footprint of this phase ~~more difficult~~ rather than being able to directly assess EV impact on a large scale, representative models must be produced. These models, such as the one created by the National Renewable Energies Lab

charging/discharging efficiency due to increasing resistance, requiring battery replacement when the capacity is dropped to battery degradation limit.

Essentially, as a battery degrades, its efficiency, places a more significant load on the electrical grid. Battery degradation can be attributed to a variety of factors, importantly, the environment and climate in which the battery operates, as well as the quality of consumer care. Extreme temperatures, notably extreme heat, are particularly detrimental to the life span of these EV batteries. Consequently, battery life spans vary from state to state under state level average driving conditions in the U.S., battery life ranges from 5.2 years in Florida to 13.3³⁰ years in Alaska.

National and Vermont State Emission Averages. The U.S. Department of Energy and National Renewable Energies Lab estimate that nationally, the average fully electric vehicle emits 12.3 metric tons of CO₂.

could be reduced by up to thirty percent if the manufacturer utilizes salvaged metals rather than virgin materials⁴⁷

Conclusion

Determining the carbon footprint of electric vehicle batteries involves assessing three distinct phases of its lifecycle: cradle-to-gate, well-to-wheels, and end-of-life. The factors that influence the amount of greenhouse gasses released during each phase are highly variable, which complicates efforts to calculate net emissions.

A review of the current literature highlights the differing methodologies employed in lifecycle assessments of the cradle-to-gate phase and the diverse range of conclusions they produce. However, an aggregated approach points to cell manufacture as the primary driver of emissions in battery production.⁴⁸ On average, the production of sized batteries suitable for plug-in hybrids typically generate between 1.2 metric tons and 2.6 metric tons of greenhouse gas (GHG) emissions. For comparison, a 2016 electric car (EV) emits 150 lbs (68 kg) of GHG per 100 miles (161 km) driven. The 2016 Toyota Prius (EV) emits 130 lbs (59 kg) of GHG per 100 miles (161 km) driven. The 2016 Ford Focus (EV) emits 110 lbs (50 kg) of GHG per 100 miles (161 km) driven. The 2016 Chevrolet Volt (EV) emits 90 lbs (41 kg) of GHG per 100 miles (161 km) driven. The 2016 Nissan Leaf (EV) emits 70 lbs (32 kg) of GHG per 100 miles (161 km) driven. The 2016 Tesla Model S (EV) emits 50 lbs (23 kg) of GHG per 100 miles (161 km) driven. The 2016 Tesla Model X (EV) emits 50 lbs (23 kg) of GHG per 100 miles (161 km) driven. The 2016 Tesla Model 3 (EV) emits 50 lbs (23 kg) of GHG per 100 miles (161 km) driven. The 2016 Tesla Model Y (EV) emits 50 lbs (23 kg) of GHG per 100 miles (161 km) driven. The 2016 Tesla Model S Plaid (EV) emits 50 lbs (23 kg) of GHG per 100 miles (161 km) driven. The 2016 Tesla Model X Plaid (EV) emits 50 lbs (23 kg) of GHG per 100 miles (161 km) driven. The 2016 Tesla Model 3 Plaid (EV) emits 50 lbs (23 kg) of GHG per 100 miles (161 km) driven. The 2016 Tesla Model Y Plaid (EV) emits 50 lbs (23 kg) of GHG per 100 miles (161 km) driven.

The potential for even greater reduction of an EV carbon footprint merges with the development of optimized networks and end-of-life processing. Several industrial techniques for reclaiming materials of value are employed, typically in tandem. Each method's energy intensity, efficiency, and production of waste varies due to the wide array of chemistries and designs used in lithium
