

ABSTRACT

	This study intended to demonstrate patterns in growth production of <i>Betula papyrifera</i> growing at elevations of 730, 820, 910, and 1000 meters in Underhill, Vermont. <i>Betula papyrifera</i> competes well at upper elevations on mountains, and is tolerant to cold weather and extreme conditions while intelerant to light limitation.
	extreme conditions while intolerant to light limitations. Production, calculated as dbh/age, was therefore hypothesized to decrease with increasing elevation because less ferrouble.

INTRODUCTION: Paper birch, Betula papyrifera, is a northern species adapted to cold climates. Its range is hound by the 130 Inly isotherm. In general the alimete where many time to a

sigmmers and long cold winters during which the ground is covered with

top 3cm of the mineral soil, where concentrations of calcium, nitrogen, phosphorous,

elevation (White-- 1000 a ...

for every 100m increase in elevation in the mountains of the Northeast (Marchand, 1987).

Along with this decrease there is an increase in precipitation of about 2.9cm per 100m increase in elevation (Whitney, 1988). All of this has a telling influence on tree growth. On Mount Mansfield it is hypothesized that overall productivity of *Betula papyrifera* across size classes will decrease with elevation. This is expected because with an increase in elevation environmental factors become harsher. The most obvious effect of lower temperature is a reduction of chemical and biological reaction rates that slow all life processes, even for organisms adapted to growing

METHODS AND MATERIALS

Betula papyrifera was sampled on the western slope of Mount Mansfield (Underhill,
Vermont) at four elevations working off the Teardrop trail. These elevations were 730m, 820m,
910m, 1000m. These elevations were determined by using an altimeter. A compass was used to
determine the direction of each transect traveled. The 730m transect followed the direction of
NROE, the 820m transect followed a direction of NROE, the Q10m transact followed a direction of

were between sites. Results included comparisons of pH, available phosphorus, reserve phosphorus, potassium, calcium, and aluminum at each elevation and are represented by bar graphs. Any differences will give insight as to the available nutrients on each site which could relate to growth productivity.

of production rates is observed for all the other elevations showing no trends of maximum production for any aged tree at any elevation.

	Age specific production was evaluated in a different way by graphing production vs dbh							
	size classes (Figure 4) Again maximum production levels are observed to not independently of

production rate that may or may not represent the real production rate at that elevation. Thus we can not accurately assume production went down for the first three elevations.

There are some possible explanations as to why overall production (Figure 1) responded the way it did. One explanation could be attributed to the soil conditions at each site. The amount of calcium (figure 6) and available phosphorus (Figure 7) showed patterns similar to that of the overall production rates. Both calcium and phosphorus are highest at 730m and decrease

may be and it is then that high production occurs. These gap disturbances can and do occur at any elevation and because Betula papyrifera competes well at high elevation and in harsh conditions, production would increase in response to new light regimes. An interesting study

similar nature produce better at higher elevations than low elevation. This would be similar to
